20. ABSTRACT (Continue on reverse side if necessary and identify by block number)  The southern part of the Ohio waters of Lake Erie between Conneaut and Marblehead was surveyed in August of 1977 and 1978 to acquire knowledge of the nature, distribution, and geometry of the lake deposits. Primary data consist of 576 kilometers of seismic reflection trackline profiles and 58 vibracores ranging from 0.7 to 6.1 meters long. About 23 percent of Ohio's part of Lake Erie was covered by the survey.		

(Continued)

Devonian shale overlain by Quaternary glacial tills and postglacial deposits underlies most of the survey area. In general, the shale is exposed nearest the shore and is succeeded offshore by till and postglacial deposits. The shale surface is commonly more irregular than the till and postglacial deposit surfaces; slopes on the lakeward dipping shale surface range from about 5 to 20 meters per kilometer.

Pleistocene tills--both basal and flow tills--also underlie most of the survey area with extensive exposures between Fairport Harbor and Avon Lake and off Lorain. Interlaminated silts and clays are interbedded with the flow till in some cores; three cores contain both basal and flow tills. The tills are made up largely of silt and clay-size particles composed of quartz and illite. The till has a flatter and more uniform surface than that of the underlying shale, with lakeward slopes ranging from about 1 to 4 meters per kilometer. The till varies in thickness from 0 to 26 meters and thickens lakeward at about 5 meters per kilometer.

Sand, muddy sand, sandy mud, and mud are the four principal postglacial deposits. These deposits commonly lie lakeward and overlie rock and till. In general, the coarser deposits lie nearest the shore. However, the two principal sand deposits at Fairport Harbor and Lorain-Vermilion are well offshore. Also, the finer deposits are found closer to shore and in shallower water west of Cleveland. Combined postglacial deposit thicknesses range from 0 to 22 meters and like the till, the postglacial sediment thickens lakeward.

The tills were first deposited on an irregular, erosional shale surface. Till deposition continued intermittently on both shale and previously deposited till until eastward retreat of the last Wisconsinan glacier from the Erie basin. Drainage of the lake ponded west of the glacier then exposed the till to subaerial erosion which led to the formation of stream channels in the till off Lorain and Fairport Harbor. Isostatic rebound of the outlet then led to a rise in lake level with associated erosion and deposition along the expanding lakeshore, which tended to smooth the till surface. The early postglacial (Holocene) deposits, which accumulated during the rise in lake level and cover the underlying till and shale, were deposited in a complex of fluvial, deltaic, and lacustrine environments. Modern lacustrine muds are now being deposited over these early Holocene deposits.

## PREFACE

This report is one of three reports which describe results of the Inner Continental Shelf Sediment and Structure (ICONS) study of southern Lake Erie. The first report (Williams, et al., 1980) deals with the sand resources in Ohio and the second report (Williams and Meisburger, 1982) provides survey results from Pennsylvania. The primary objective of the ICONS program is to locate and delineate sand and gravel deposits suitable for beach nourishment and restoration (Duane, 1968). The work was carried out under the U.S. Army Coastal Engineering Research Center's (CERC) Barrier Island Sedimentation Studies work unit, Shore Protection and Restoration Program, Coastal Engineering Area of Civil Works Research and Development, in cooperation with the Ohio Department of Natural Resources, Division of Geological Survey (DGS).

The report was prepared by Charles H. Carter and Jonathan A. Fuller, Geologists, under the general supervision of H.R. Collins, Chief, DGS, and by S. Jeffress Williams and Edward P. Meisburger, Geologists, under the general supervision of Dr. C.H. Everts, Chief, Engineering Geology Branch, and Mr. N. Parker, Chief, Engineering Development Division, CERC. Data collection was conducted by CERC and DGS with the assistance of U.S. Army Engineer Districts, Buffalo and Mobile, and the U.S. Army Engineer Waterways Experiment Station (WES).

The authors acknowledge the assistance of a large number of people who contributed to the success of this study. J. May, J. Forbes, and D. Andrews of WES operated the seismic reflection equipment; E. Lagrone of the Mobile District operated the vibracore equipment; and M. Chambers of the Buffalo District skippered the tug and scow for the vibracore operation. Within DGS, D.L. Liebhenthal skippered the boat carrying the seismic reflection equipment and the navigation system; D.E. Guy, Jr., C.L. Hopfinger, T.J. Feldkamp, J.D. Reed, and J. Vormelker positioned the transponders for the Mini Ranger; R.W. Carlton provided the X-ray diffraction analyses; and C.L. Hopfinger helped throughout with the laboratory work on the vibracores, with data compilation in the office, and with identification of the mollusks, with the aid of M.J. Camp of the University of Toledo. N.A. Rukavina (Environment Canada) provided helpful comments on parts of the report. In addition, G.P. Hall and J.C. Dixon of the Ohio Department of Transportation provided the Atterberg limits, and T.L. Lewis of Cleveland State University had the radiocarbon work done. D.A. Prins of CERC served as field survey chief during both data collection phases, and D.J. Benson, formerly of DGS, helped plan the field surveys and took part in the seismic reflection survey. Lastly, C.H. Everts and H.R. Collins made constructive reviews and their comments are appreciated.

Original copies of all seismic data are stored at CERC. Cores collected during the field survey program in Ohio are in a repository at the University of Toledo, under agreement with CERC. Requests for information relative to these items should be directed to CERC or the Department of Geology, University of Toledo.

Technical Director of CERC was Dr. Robert W. Whalin, P.E., upon publication of this report.

Comments on this publication are invited.

Approved for publication in accordance with Public Law 166, 79th Congress, approved 31 July 1945, as supplemented by Public Law 172, 88th Congress, approved 7 November 1963.

<sup>1</sup>To obtain Celsius (C) temperature readings from Fahrenheit (F) readings, use formula:  $C = (5/9) (F - 32)$ .

To obtain Kelvin (K) readings, use formula:  $K = (5/9) (F - 32) + 273.15$ .

REGIONAL GEOLOGY OF THE SOUTHERN LAKE ERIE (OHIO) BOTTOM:  
A SEISMIC REFLECTION AND VIBRACORE STUDY

by

*Charles H. Carter, S. Jeffress Williams,  
Jonathan A. Fuller, and Edward P. Meisburger*

I. INTRODUCTION

1. Background and Scope.

The construction, improvement, and periodic maintenance of beaches and dunes by the placement (nourishment) of suitable sand along the shoreline is an important means of counteracting coastal erosion and enhancing recreational facilities. However, it has become increasingly difficult in recent years to obtain suitable sand from traditional sources such as lagoons and inland deposits because of economic and ecological factors. This problem led the U.S. Army Coastal Engineering Research Center (CERC) to initiate a search for offshore sand deposits. Exploratory efforts to locate and inventory deposits suitable for future fill requirements began in 1964 with a survey off the New Jersey coast (Duane, 1969). Subsequent data collection surveys have included the Inner Continental Shelf areas off New England, Long Island, Delaware, Maryland, Virginia, Florida, the Cape Fear region of North Carolina, eastern Lake Michigan, and southern California. This program, formerly known as the Sand Inventory Program, is now known as the Inner Continental Shelf Sediment and Structure (ICONS) program.

The type of data collected for the ICONS program is not only useful in locating potential borrow areas but is of further value in providing geological information for planning, design, and environmental impact evaluation of coastal engineering works. The results of the ICONS studies are normally presented in two separate but complementary reports: one covering sand resources, the other covering the regional geology.

This study is unique from the previous ICONS studies in that it was conducted in cooperation with a State geological survey, the Ohio Department of Natural Resources, Division of Geological Survey (DGS). The report deals primarily with the bottom and subbottom deposits in the Ohio waters of Lake Erie as mapped largely from high-frequency seismic reflection profiles and vibracores between Conneaut (at the Ohio-Pennsylvania border) and Marblehead. The report does not include the reach between Marblehead and Toledo. Seismic profiling of this reach was done, but no vibracores were taken and the seismic records are difficult to interpret because of the lack of well-defined reflectors. The lack of well-defined reflectors on the records between Vermilion and Marblehead also precluded mapping of the subbottom deposits along this stretch of shore. This report follows a report on sand resources in Ohio (Williams, et al., 1980) and another report on the Pennsylvania part of Lake Erie (Williams and Meisburger, 1982).

The study area encompasses a zone ranging from 1 to 16 kilometers offshore between Conneaut and Marblehead (Fig. 1). Survey coverage of the area is shown

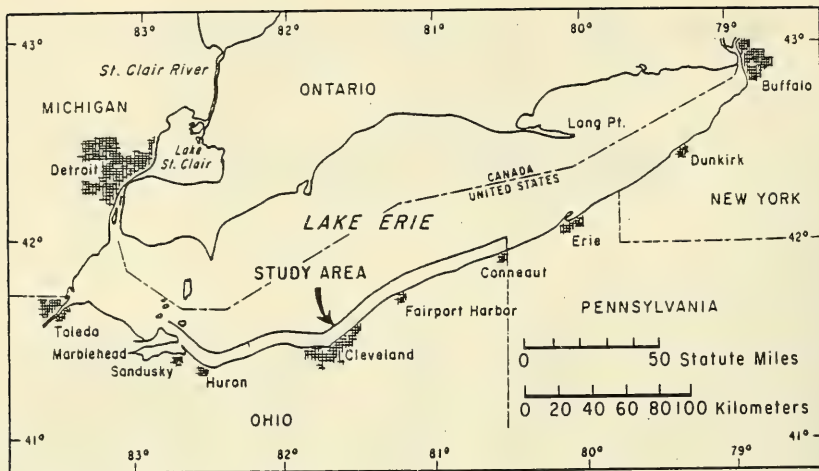

Figure 1. Lake Erie study area, from Conneaut to Marblehead, Ohio.

in Figures 2 to 7. Data collected for this study consist of 576 kilometers of seismic reflection trackline profiles, taken in August 1977, and 58 vibracores ranging from 0.7 to 6.1 meters long, taken in August 1978. About 23 percent of Ohio's open lake part of Lake Erie (7481 square kilometers) was covered by the seismic reflection survey between Conneaut and Marblehead.

The survey data in this report were supplemented in places by previous DGS work. Vertical control was obtained from National Ocean Survey (NOS) water level gage data for Lake Erie; water depths are referenced to low water datum (LWD), which is 173.3 meters above mean water level at Father Point, Quebec (International Great Lakes Datum (IGLD), 1955). Mean lake level in both August 1977 and August 1978 was about 1 meter above LWD. This study is basically reconnaissance in nature, as seismic line spacing and orientation and core spacing density preclude a detailed evaluation of the bottom and subbottom deposits. However, because of the relatively flat-lying nature of the deposits, extrapolation between tracklines can be made with a fair degree of confidence.

## 2. Field Procedures.

a. Geographic Positioning System. A radar-type electronic positioning system, the Motorola Mini-Ranger III, was used to determine position of the research survey vessel during the seismic survey (phase I) and the vibracoring (phase II). The system determines the position of the survey vessel with respect to two known reference points on shore and is restricted to line-of-sight operation. The basic system consists of a master mobile unit mounted onboard the vessel and two shore-based transponders. The master unit triggers reply pulses from the transponders; each transponder pulse is received separately and the elapsed time between the transmitted pulse and the individual transponder reply pulse is converted to a measurement of distance. Each distance (range) from the two transponders at the known shore stations is displayed in turn on the range console. This range information, together with the known locations of the shore stations, is then trilaterated and plotted on hydrographic charts to obtain the position (fix) of the survey vessel.

Figure 2. Trackline location map, Ohio-Pennsylvania State line to east of Fairport Harbor.

Figure 4. Trackline location map, Northeast Yacht Club to Avon Point.

Figure 5. Trackline location map, Avon Point to Vermilion.

Figure 6. Trackline location map, Vermilion to Cedar Point.

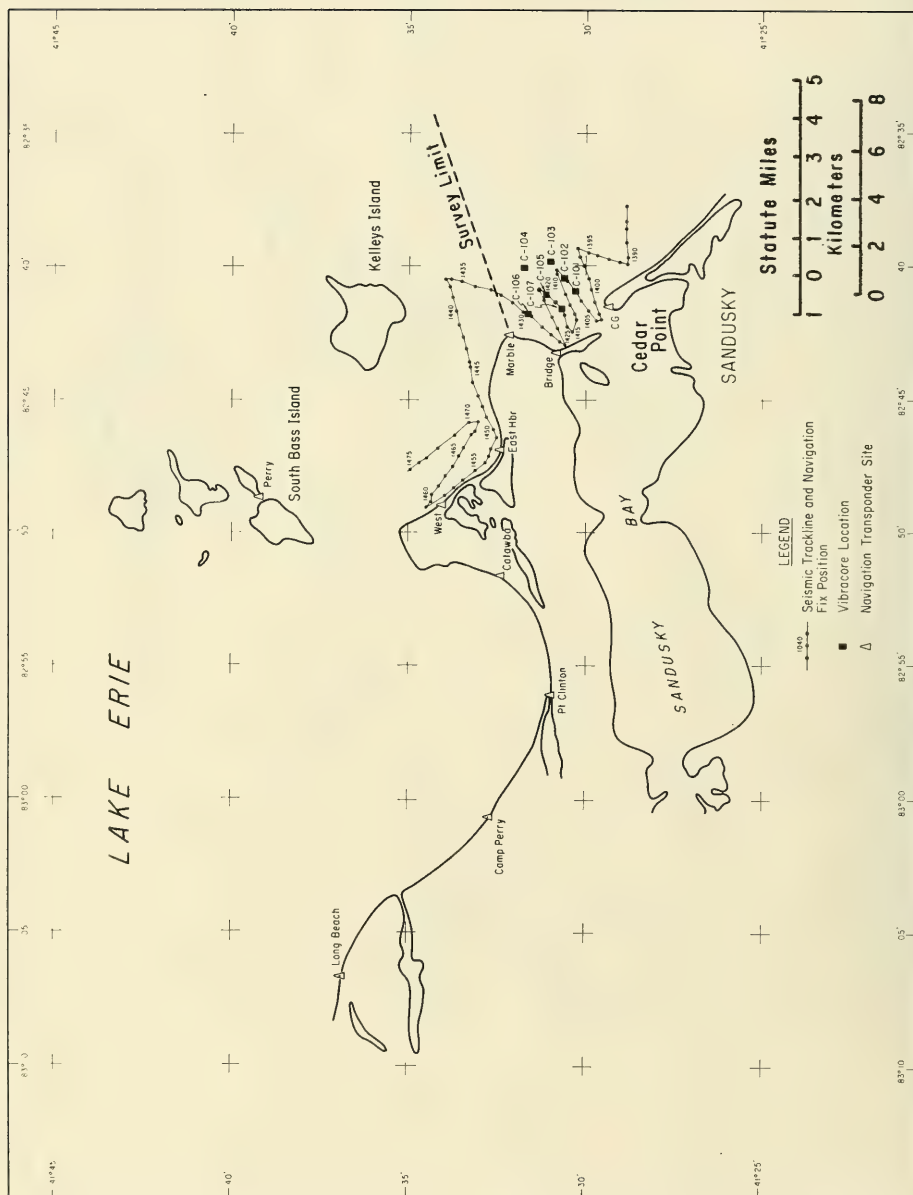

Figure 7. Trackline location map, Cedar Point to Long Beach.

Navigational fixes during the seismic survey were obtained about every 2 minutes and each fix was keyed to the seismic records by an event mark on the records.

b. Seismic Reflection Profiling. Seismic reflection profiling is widely used to delineate geologic features on land and over water. In this study, repetitive high-energy sound pulses were generated near the water surface to produce seismic waves, which reflected off the geologic features; these waves were received and recorded on paper by a recorder aboard the survey vessel to produce a cross section representing the features at and below the lake bottom.

The seismic reflection data were obtained by towing the sound-generating and receiving instruments behind the DGS research vessel, *GS-1* (Fig. 8), which followed predetermined survey tracklines (Figs. 2 to 7). In phase I of this study, two seismic subbottom profiling systems were used simultaneously: an Ocean Research Equipment, Inc. (ORE) 3.5-kilohertz pinger system and an Edgerton, Gremerhausen and Greer (EG&G), Inc. UNIBOOM system. The pinger records were of little use because of their lack of resolvable reflectors, whereas the UNIBOOM records were generally good. The inshore boundary of the survey was about 1 kilometer from shore and the offshore boundary was about 7 kilometers offshore. The nearshore survey water depths were about 7.5 meters, which is about the minimum depth for obtaining good-quality seismic profiles; the offshore water depths were about 14 meters. Information on various seismic profiling techniques is discussed in Ewing (1963), Moore and Palmer (1967), Barnes, et al. (1972), and American Association of Petroleum Geologists (1977).

Figure 8. The DGS Research Vessel *GS-1* used to tow the seismic equipment and locate core sites.

c. Coring Equipment. A pneumatic vibratory coring device designed to obtain continuous sediment cores a maximum of 6.1 meters long was used in the phase II survey operation (Fig. 9). The apparatus is equally effective in penetrating and recovering granular and cohesive sediments; however, a stony till is not easily penetrated and the core barrel will not penetrate coherent rock. The core rig consists of a 10-centimeter steel core barrel, clear plastic inner liner, shoe and core catcher, and a pneumatic driving head attached to the upper end of the barrel. These elements are enclosed in a quadrapod-like frame with four articulated legs which rest on the lake bottom. An aluminum H-beam and frame serve as a support structure and guide for the vibrator head and core pipe as the core barrel penetrates the lake bottom. The lack of rigid attachment of the coring device to the surface vessel allowed limited motion of the vessel during the actual coring processes. Power was supplied to the pneumatic vibrator head by a flexible hose line connected to a large-capacity (118 liters per second) air compressor. After coring was completed, the assembly was hoisted onboard the vessel, the liner containing the core was removed, samples from the top and bottom of the core recovered, the ends sealed, and the core carefully marked for orientation and identification. The historical development of vibratory coring equipment is discussed by Tirey (1972).

Figure 9. A 6-meter-long vibratory coring apparatus used to collect sediment cores is shown being lifted off the platform for deployment on the lake floor.

A 36-meter-long scow from the U.S. Army Engineer District, Buffalo, was used as the platform for phase II coring. The scow was transported by the Corps tugboat *Washington* (Fig. 10).

Figure 10. The U.S. Army Engineer District, Buffalo, tugboat *Washington*.

d. Data Collection. Before the fieldwork began, seismic survey tracklines were plotted on navigation charts of the survey area. Position, spacing, and length of the tracklines were determined by several factors. The primary concern was spacing the lines to achieve maximum coverage of the study area within the limits of time and budget. After the survey tracklines were selected, the locations of the shore stations for the navigation system were determined. Of high priority were stations at elevated positions (for adequate line-of-sight), which also offered good triangular position in relation to the survey vessel and adjacent shore stations. (Acceptable results are achieved when the angle of range intercept of the vessel is greater than  $30^{\circ}$  and less than  $150^{\circ}$ ; optimum range angle intercept is  $90^{\circ}$ .) A total of 32 shore navigation stations were used along 207 kilometers of coast from Conneaut to Marblehead. Positions and spacing of the tracklines were altered at times to gather additional information on geologic features such as buried stream channels, sediment contacts, and probable lake bottom exposures of sand.

Interpretations of the seismic profile records were made to select coring sites with the greatest potential for sand and subsurface information. These records were visually examined and marked to establish the primary geologic features (e.g., regional sedimentary reflectors, sediment contacts, buried stream channels). Selected acoustic reflectors were then mapped to provide areal continuity of horizons considered significant because of their areal extent and relationship to the general structure and geology of the study area. The use of seismic data to interpret geologic conditions before selecting the core sites maximizes the usefulness of both sources of data and provides the most efficient use of funds.

During phase II, the vessel *GS-1* was used to relocate fix positions selected as coring sites by duplicating the range values from the shore stations. The *GS-1* first maneuvered until one of the ranges was duplicated and then an arc was run on that range until the other range was intersected, at which time an anchored float was used to mark the core location. Core sites were located and marked in this manner because of the limited maneuverability of the scow. The *GS-1* crew located a core position in minutes and dropped a float marker; the tug and scow then moved in on the marker, anchored, and the core rig was lifted from the deck of the scow and set on the lake bottom. Meanwhile, the *GS-1* proceeded to the next core site. Once the core rig was on the bottom, the core barrel was driven into the lake bottom sediments; within about 15 minutes the coring was completed and the apparatus was lifted back onto the scow. The core liner containing the sediment was removed from the barrel and small reference samples were obtained from the top and the bottom of each core. The liner was then capped and sealed, labeled, and a general description of the samples was made. The scow was then moved to the next coring location. While underway, the corer was reassembled and loaded with a new liner. In general, the corer penetrated the lake bottom deposits quite easily; however, penetration in stony till and in some well-sorted, medium-grained sands was poor.

### 3. Office and Laboratory Procedures.

After completion of the data collection, the navigational fix marks, ship trackline positions, core sites, and shore stations were plotted to show the coverage in the survey area (Figs. 2 to 7). The cores were split longitudinally, using a circular powersaw to cut the plastic liner and a piece of thin wire to cut the sediment. As soon as the core was opened it was color typed using the Munsell color system (Munsell Soil Color Charts, 1954 ed., Munsell Color, Inc., Baltimore, Md.). Color typing was immediately followed by sampling for natural water determinations (sample is weighed, dried, and reweighed), by unconfined compressive and shear-strength measurements (using hand-held Soiltest instruments), and by detailed descriptions (see App. A). The unsampled half of the core was wrapped in plastic for storage. After the sampled half had partially dried (a day or two), the description was checked, photos of representative units were taken, and additional sampling was done if necessary.

Three principal techniques were used for the grain-size analyses: rapid sand analysis (RSA) for the finer sands (U.S. Army, Corps of Engineers, Coastal Engineering Research Center, 1977), sieve analysis at 0.5-phi intervals for the coarser sands and fine gravel (Folk, 1974), and pipet analysis for the samples containing appreciable clay- and silt-size particles (Folk, 1974) (App. B). In addition, 22 clay samples were analyzed by X-ray diffraction (App. C), and general sand-grain mineralogy was determined with a binocular microscope using a feldspar stain technique (Gross and Moran, 1970). Atterberg limits were determined for 29 fine-grained samples (App. D), and two radiocarbon-14 ages were determined from wood samples in core 62. Mollusks from selected samples were identified generally to species level (App. E).

### 4. Seismic Interpretation.

Seismic reflections from the shale and till surfaces were extensive enough in the subbottom to be mapped throughout most of the study area. The shale reflector generally is broken and irregular but well defined with closely

spaced internal reflectors which either intersect the main reflector at a low angle or parallel it in a regular pattern (Fig. 11). On the other hand, the till reflector generally is continuous and not as irregular nor as well defined as the shale reflector. In addition, irregular but fairly continuous internal reflectors are fairly common in the till (Fig. 12). The shale and till reflectors were mapped at two confidence levels. The first confidence level was used where the reflector was well defined on the seismic record. The second confidence level was used where the reflector was not as well defined but its position could be reasonably well inferred from the overall geologic setting and character of the reflector. In addition, the echo character type of the surface sediment, in conjunction with reference sediment samples, was used to map the surface sediment. Seven surface echo character types were defined: rock, till, sand, muddy sand, sandy mud, mud, and rock waste (Table 1).

Following the mapping of the reflectors, acoustic traveltimes were measured to determine sediment thicknesses (App. F). The velocities of sound through the till and postglacial sediment are used to convert these measurements into sediment thickness. The velocity of sound in water was calculated to be about 1.54 kilometers per second from measured depths at several core locations (App. G). The average velocity in the postglacial sediment was calculated to be about 1.3 kilometers per second in a similar way by using the thickness of the postglacial sediment in the vibracores (Apps. H and I). A velocity for the till was not calculated because none of the cores penetrated till to rock; however, laboratory work by Morgan (1964) suggests that 1.8 kilometers per second is a realistic velocity for Lake Erie till so this value was used in the calculations.

## 5. Previous Studies.

The first comprehensive bottom sediment study of the Ohio part of the central Lake Erie basin was done by Hartley (1961). Bottom grab samples were taken on 1.6- or 3.2-kilometer grids and some subbottom sampling was done by coring or jetting. Hartley's work provided important data that were used extensively in the planning stages of this study. Shore and nearshore deposits within 610 meters of the shoreline were mapped in the 1970's as part of DGS's county shore erosion studies (Benson, 1978; Carter and Guy, 1980); this information was used in the current study to map the sediment adjacent to the shore. Also, several hundred kilometers of seismic reflection profiles and 32 borings and vibracores were collected in a rectangular nearshore area off Cleveland (Dames and Moore, 1974).

Three shallow seismic reflection surveys of central Lake Erie have been reported (Morgan, 1964; Lewis, 1966; Wall, 1968). The works by Morgan (1964) and Wall (1968) are too general to be of use, whereas the work by Lewis (1966) is sufficiently detailed, particularly on the geologic history of the lake, and of use.

## II. PHYSICAL SETTING

### 1. Introduction.

The Lake Erie basin is underlain by middle Paleozoic sedimentary rocks that are overlain by Pleistocene- and Holocene-age deposits. The Pleistocene deposits

Table 1. Surface-sediment echo character and their interpretation.

Echo character	Sediment interpretation	Letter designation
Very poor multiple, <sup>1</sup> smooth surface, mostly transparent, may have continuous, multiple, parallel internal reflectors.	Soft, nearly fluid mud	M
Very poor to poor multiples, <sup>1</sup> slightly irregular surface (rougher than M), nontransparent (a noisy record).	Sandy mud	X
Good multiples <sup>1</sup> (commonly two to three), smooth to slightly irregular surface (similar to X), nontransparent.	Muddy sand	O
Fair multiples, <sup>1</sup> hummocky to gently rolling but smooth surface, commonly nontransparent.	Sand	S
Poor to good multiples (mostly fair), smooth or irregular surface (in between S and R), commonly irregular internal reflectors.	Clay and clay with gravel (probably till)	T
Fair to good multiples (commonly three or more), commonly a broken, irregular surface (may look similar to T), and may have closely spaced discontinuous, internal reflectors.	Rock (probably shale)	R
Fair to good multiples and a jagged, irregular surface.	Rock waste (shale derived from a harbor excavation)	RW

<sup>1</sup>Very poor multiple: a discontinuous multiple if present.

Poor multiples: one to two multiples; the first multiple is commonly discontinuous.

Fair multiples: one to two multiples; the first multiple is commonly continuous.

Good multiples: two to seven multiples; the first and second multiples are commonly continuous.

consist largely of glacial till and the Holocene deposits consist largely of fine-grained lake sediments. About 14,000 years before present (B.P.) a glacial lake occupied the Lake Erie basin to an elevation of about 244 meters above sea level (Sly, 1976). Within the next 1,400 years or so, lake level fluctuations of a few tens of meters took place as the receding glacier, in a series of retreats and advances, alternately exposed and buried different lake outlets. The glacial activity ended about 12,600 years B.P. with retreat of the last Wisconsinan glacier. This allowed the lake waters to discharge northeastward across the Niagara escarpment, which at that time was depressed due to the weight of the glacier. Because this outlet was about 40 meters below present lake level, the level of early Lake Erie was at about 134 meters above sea level. Subsequent isostatic rebound of the escarpment at the outlet led to the filling of the lake to its present elevation of about 174 meters above sea level.

## 2. Shore.

The shore from Conneaut to Huron consists of moderate to high relief (3 to 20 meters) shale and till slopes and bluffs commonly capped by old lake deposits. The shale is exposed for appreciable lengths above or near lake level from Conneaut to Fairport Harbor, near Euclid (Moss Point), between Cleveland and Avon Point, and near Vermilion. The shore from Huron to Marblehead consists of low relief (<2 meters) barrier beaches and laminated clay banks. The shore at Marblehead consists largely of moderate relief (3 to 6 meters) dolostone and limestone banks.

Beaches make up a fragmented band that front about 50 percent of the shore in the study area. The beaches are commonly narrow (<15 meters wide) and consist primarily of sand, although there are pocket beaches of cobbles in places where the shore is composed of rock. In addition, there are about 3,000 shore protection structures consisting largely of groins and seawalls scattered along the shore.

## 3. Offshore.

Lake Erie is the shallowest of the five Great Lakes with an average depth of about 19 meters and a maximum depth of 65 meters. The nearshore slopes are generally less than 1°; in the study area within 1 to 2 kilometers of the shore the slope is about 0.25°, except between Fairport Harbor and Avon Point, where the slope is about 0.50°. Offshore the slopes become gentler with a slight decrease in slope from east to west; the area off Lorain-Vermilion is the principal exception. In this area the offshore bottom rises to form a subtle ridge (Pelee-Lorain ridge) which extends across the lake to Point Pelee, Canada. Sand and gravel, generally less than 2 meters thick, cover much of the nearshore (<1 kilometer offshore) bottom; most of the bottom farther offshore is made up of fine-grained postglacial sediment, rock, till, or glaciolacustrine clay (Verber, 1957; Hartley, 1961; Williams, et al., 1980). In general, the distribution of these offshore deposits (to the international boundary) can be divided into two areas: from Conneaut to Fairport Harbor, a band of shale is bordered offshore by sand and finer postglacial sediment; from Fairport Harbor to Marblehead, a band of sand and gravel, till, or rock (mostly shale) is bordered offshore by finer, postglacial sediment except for till in the Cleveland area and sand and gravel in the Lorain-Vermilion area.

### III. BOTTOM DEPOSITS

#### 1. Introduction.

Shale, till, and postglacial sediment ranging from sand to mud make up most of the bottom deposits. Shale underlies most of the Ohio part of Lake Erie. The shale is overlain by glacial tills that are overlain by postglacial deposits. In general, the shale is exposed nearest the shore and succeeded offshore by the tills and postglacial deposits.

#### 2. Shale.

The contact between the Devonian limestones and dolomites to the west and the Devonian shales to the east lies between Huron and Sandusky (Bownocker, 1920). The northeast trend of this contact, a gentle southeast dip, and shore and nearshore exposures indicate that the Devonian Ohio Shale underlies most of the survey area. In northern Ohio, the shale is made up of two carbonaceous, blue-black shale members separated by a largely noncarbonaceous, blue-gray, silty shale member (Hoover, 1960).

Shale is exposed close to the shore in a continuous 2-kilometer-wide band between Conneaut and Fairport Harbor, in a broken 1- to 2-kilometer-wide band between Cleveland and Lorain, and in a continuous 2- to 3-kilometer-wide band off Vermilion. The echo character of the shale surface on the seismic records ranges from smooth to irregular (Fig. 11). In the subsurface, the shale reflector could be mapped along most of the tracklines; however, the reflector was not apparent in places off Ashtabula, Fairport Harbor, Cleveland, and west of Vermilion (Fig. 13).

The shale surface slopes lakeward between Conneaut and Ashtabula at about 10 meters per kilometer. West of Ashtabula, the slope is about 5 meters per kilometer, decreasing to about 2 to 3 meters per kilometer at Fairport Harbor and then increasing to about 10 meters per kilometer at Moss Point. The seismic records do not show a shale reflector between Moss Point and west Cleveland. From west Cleveland to Avon Point the slope is 15 to 20 meters per kilometer; from Avon Point to west Vermilion the slope is gentler, about 4 to 6 meters per kilometer. The irregular nearshore shale surface characterized by these variable slopes is further exemplified by a major buried river valley (about 90 meters deep) entering Lake Erie at Cleveland (Crowell, 1979). In addition, there are major valleys eroded into the shale at Huron (Stein, 1962) and Lorain (Pree, 1962).

#### 3. Till.

Till overlies the Devonian Ohio Shale over most of the region covered by the tracklines (Fig. 14). It can generally be characterized as a hard, stony, unstratified deposit interpreted as basal till (Fig. 15; gravelly clay in App. A) or a soft, clay-rich, commonly stratified deposit interpreted as flow till (Fig. 16). Some of the till sections (e.g., cores 95, 98, and 100) contain interlaminated silts and clays resembling varves (Fig. 17; clay in App. A); cores 92, 98, and 99 contain both basal and flow till. The tills are made up largely of silt- and clay-size particles composed of quartz and illite. Detailed information on the texture, composition, and engineering properties of the till is in Appendixes B and C; Table 2 is a summary of the information.

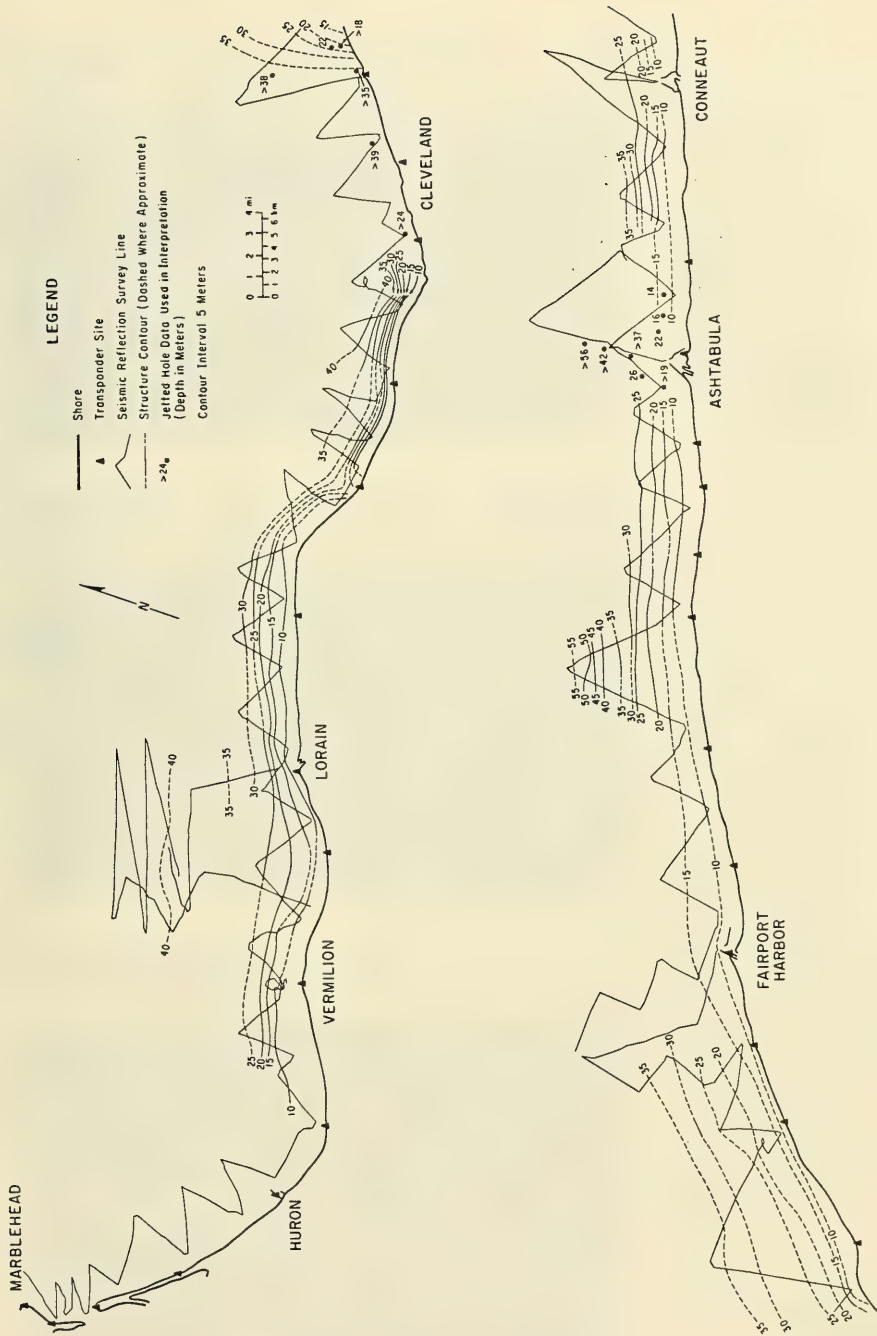

Figure 13. Rock structure contour map as interpreted mainly from the seismic reflection records. Contours in meters below survey lake level of about 174.3 meters (IGLD, 1955). The overlying sediment thickness was determined from till and postglacial sediment thicknesses.

liquid limit	26.7	--- <sup>1</sup>	32.0	29.2
plasticity index	9.1	---	11.8	10.4

<sup>1</sup>No data.

Two types of basal till were found in the cores. An olive-gray basal till was found between Ashtabula and Fairport Harbor (cores 54, 55, 60, 61, and 70) and between Avon Point and Huron (cores 77 to 80, 82, 86, 98, and 99); a yellowish-gray basal till was found in the Lorain-Vermilion area (cores 84, 85, 92, 97, and 98). The yellowish-gray basal till overlies the olive-gray basal till in core 98.

Flow till is found in the Cleveland area and between Lorain and Huron (cores 71 to 76, 81, 82, 92, 95, 96, 98, 99, and 100). A nearly structureless olive-gray flow till with minor pea gravel and reddish-brown clay pods was found in the Cleveland area (cores 71 to 76). The flow till between Lorain and Vermilion (cores 81, 92, 95, 96, 98, 99, and 100) has contorted flow banding and ranges in color from olive gray to dark yellowish brown. This flow till overlies a basal till in cores 92, 98, and 99.

The basal till and flow till are exposed nearly continuously between Fairport Harbor and Avon Point and between Lorain and Vermilion. Their surface echo character on the seismic records ranges from smooth to irregular. In general, the till in the Cleveland area has a smooth surface echo character (Fig. 18); the till exposed both east and west has a more irregular surface echo character (Fig. 19).

The till surface from Conneaut to Fairport Harbor slopes lakeward at 2 to 4 meters per kilometer. Between Fairport Harbor and west Cleveland the slope is gentler, 1 to 2 meters per kilometer. From west Cleveland to Avon Point the slope is steeper but fairly uniform at 2 to 3 meters per kilometer.

- C Water-sediment interface (till)
- D First multiple

Figure 19. Seismic record showing the irregular surface echo character of the till; this section is from about 13 kilometers west of Fairport Harbor.

Off Lorain-Vermilion the surface slopes lakeward toward the Pelee-Lorain ridge at about 2 meters per kilometer to a depth of 23 meters before rising at the same slope. In general, the till surface is fairly flat in contrast to the underlying shale; however, topographic lows on the till surface were mapped off Lorain-Vermilion (Hartley, 1960) and off Fairport Harbor (Wall, 1968).

The till thickens offshore, forming a wedge on the underlying rock; till thicknesses determined from the seismic records range from 0 to 26 meters. However, data indicate a till thickness of more than 28 meters off Cleveland (Dames and Moore, 1974). Between Conneaut and Moss Point the till thickens offshore at about 4 meters per kilometer. The till at west Cleveland thickens offshore at about 31 meters per kilometer and then decreases uniformly westward to about 6 meters per kilometer at Lorain (Fig. 20).

#### 4. Postglacial Sediment.

Postglacial sediments ranging from sand to mud commonly lie lakeward of and overlie rock and till (Fig. 21). The principal exceptions are off Cleveland, where postglacial sediment is succeeded offshore by till, and west of Huron, where postglacial sediment lies adjacent to the shore. The sediments can be classified into four echo character types: sand, muddy sand, sandy mud, and mud (Table 1; Figs. 22 to 25). In addition, rock waste from harbor dredging was mapped off Ashtabula. In general, the sand is less than 0.5 millimeter in diameter and is composed largely of subangular to subrounded grains of quartz, feldspar, and rock fragments. The clay-size particles are similar in mineralogy to the clays in the till--mostly quartz, illite, and chlorite--although several samples contain montmorillonite. Macrofossils (clams and snails) were common in some cores, primarily in the coarser sediment. Specific data on the texture, composition, engineering characteristics, and fossils of these deposits are given in Appendixes B to E.

Between Conneaut and Fairport Harbor, muddy sand directly overlying shale is generally found close to shore. This sediment is succeeded offshore by sandy mud, which is commonly succeeded by mud. Between Fairport Harbor and Cleveland, with the exception of the complex Fairport Harbor area, sandy mud was the only postglacial sediment mapped at the lakeward ends of the traverses. Between Cleveland and Vermilion mud generally lies lakeward of till or rock, although coarser grained deposits lie offshore of the mud in the Lorain-Vermilion area. West of Vermilion muddy sand is commonly succeeded lakeward by sandy mud. Sand was mapped in three areas: Conneaut, Fairport Harbor, and Lorain-Vermilion; see Williams, et al. (1980) for a discussion of the sand deposits at Fairport Harbor and Lorain-Vermilion. Also, the finer sediments (mud and sandy mud) are generally found closer to shore and in shallower water west of Cleveland.

The postglacial sediment increases in thickness offshore, except off Lorain, reaching 18 meters between Conneaut and Fairport Harbor, nearly zero between Fairport Harbor and Lorain, and up to 8 meters thick between Lorain and Vermilion (Fig. 26). The thicknesses, however, are difficult to compare because of the short (<5 kilometers) seismic traverses west of Cleveland. Along the Conneaut to Cleveland reach, there is a principal difference at about 9 kilometers offshore; from Conneaut to Fairport Harbor postglacial sediment thicknesses range from 10 to 16 meters, whereas from Fairport Harbor to Cleveland there is an apparent lack of postglacial sediment. Along the

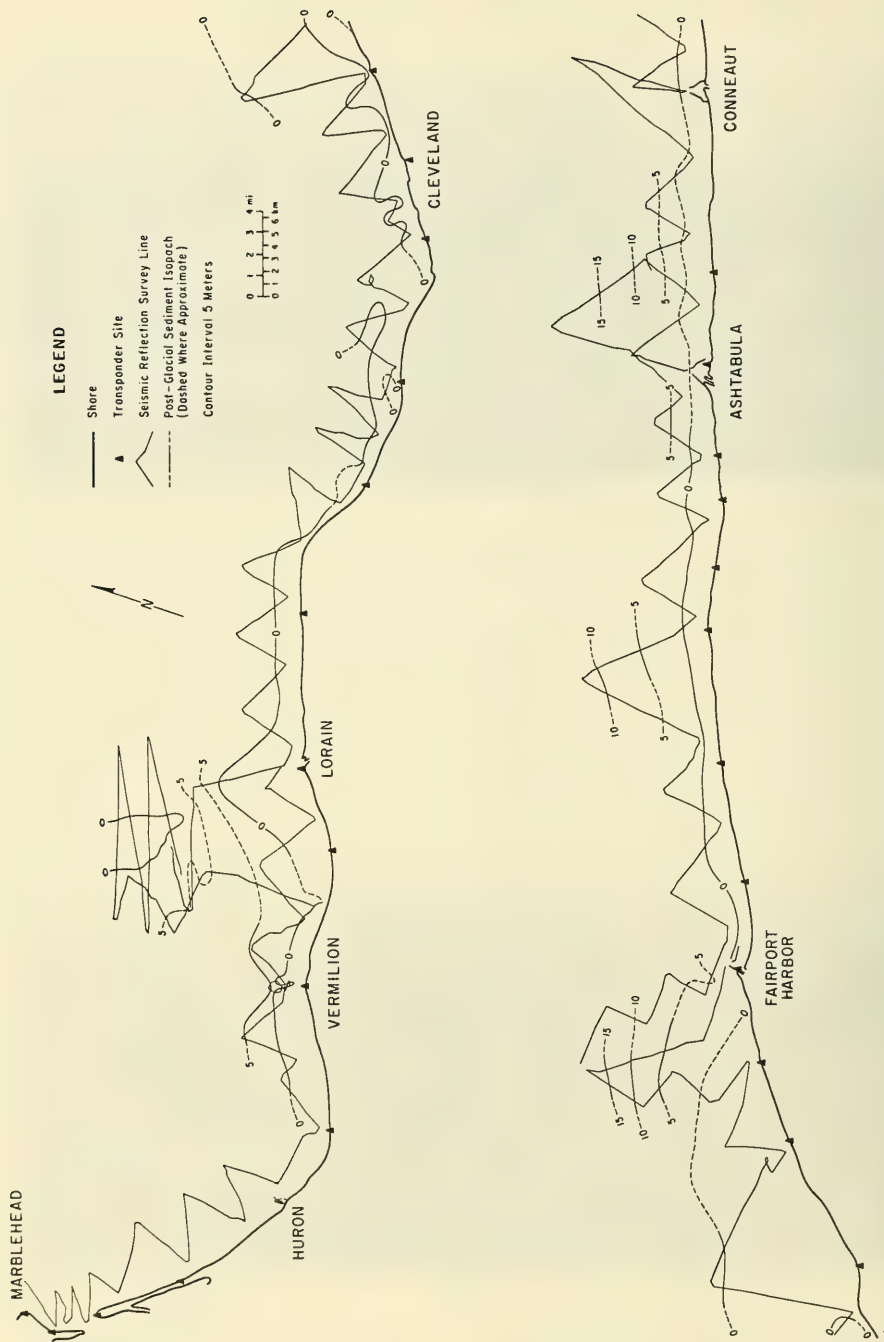

Figure 26. Postglacial sediment isopach as interpreted mainly from seismic reflection records. Contours in meters below survey lake level of about 174.3 meters (IGLD, 1955).

Cleveland to Vermilion reach, with the exception of the area offshore of Lorain, there is also a basic difference at about 5 kilometers offshore; from Cleveland to Lorain postglacial sediment thicknesses range from 0 to 2 meters, whereas from Lorain to Vermilion postglacial sediment thicknesses range from 4 to 5 meters. Offshore of Lorain, the postglacial sediment thickens to 8 meters about 8 kilometers offshore and then decreases to the north as it pinches out against the Pelee-Lorain ridge. Thus it appears that the nature and thickness of the postglacial sediment is largely controlled by the configuration of the underlying rock and till surfaces as well as by the existing wave climate.

#### IV. GEOLOGIC HISTORY

##### 1. Introduction.

Sedimentary deposits from the Devonian and the Quaternary periods are exposed in the study area. The Devonian Ohio Shale underlies most of the area except for lower Devonian carbonates near Sandusky; Quaternary glacial and interglacial Pleistocene deposits and postglacial Holocene deposits overlie the Devonian rocks. A good general overview of the Quaternary geologic history of the Lake Erie basin is given in Sly and Lewis (1972).

##### 2. Shale.

Seismic reflection profiles extending the width of the central Lake Erie basin illustrate the relatively irregular rock surface on a regional scale (see Fig. 23 in Lewis, 1966). The irregular rock surface, as well as the buried ancestral valleys of the Cuyahoga, Black, and Huron Rivers, indicates that appreciable erosion of the shale has occurred. The relative narrowness and northerly trend of these valleys, in addition to their Pleistocene fill, imply that much of the erosion took place before Pleistocene Glaciation, probably by streams.

##### 3. Till.

The relatively smooth till surface on the seismic records is judged to be the product of several Wisconsinan glacial advances and retreats with glacial and periglacial processes tending to smooth and fill irregularities in the earlier glacial deposits. This hypothesis is consistent with the physical variations in the deposits mapped from the seismic reflection records and the internal reflectors, which indicate that the till is likely made up of multiple till deposits. Field studies on both sides of the lake have documented multiple Wisconsinan tills (Dreimanis, 1970; White and Totten, 1979). Following the classifications of White and Totten (1979) and White (1979), the olive-gray basal till in the cores is interpreted to be the Titusville-Millbrook Till and the yellowish-gray basal till to be either the Lavery-Hayesville Till or the Hiram Till.

The topographic lows in the till mapped off Fairport Harbor (Wall, 1968) and Lorain-Vermilion (Hartley, 1960) are the most prominent features in the till surface. In agreement with Wall's interpretation (1968), the lows represent channels cut into the till surface by eastward-flowing streams probably following the retreat of the Erie glacier from the eastern end of the lake.

Lewis (1966) mapped two cross-lake moraines: The Eriean-Cleveland moraine and the Pelee-Lorain moraine. The Eriean-Cleveland moraine extends from Eriean, Ontario, to east of Cleveland, Ohio. The survey for the current study did not extend far enough offshore to encounter this feature, but the trend of the feature toward the U.S. shore (Fig. 21 in Lewis, 1966) indicates that the feature might be related to the broad till platform mapped west of Fairport Harbor. No evidence has been found of an end moraine along the Ohio shore that would tie into this feature. Perhaps the moraine was eroded by streams following glacial retreat or by waves and currents during the early lake stages.

The Pelee-Lorain moraine extends from Pelee Point, Ontario, to Lorain-Vermilion, Ohio. The southern part of this feature was mapped in the survey; however, as with the Eriean-Cleveland moraine, no evidence has been found of an end moraine along the Ohio shore. As an alternate hypothesis perhaps the above named tills were deposited by a glacier limited in extent to the present lake boundaries and thus are younger than the hypothesized tills.

The overall scarcity of glaciolacustrine clay may be the result of Holocene erosion. Erosion of the clay probably took place both subaerially and subaqueously following retreat of the last Wisconsinian glacier from the Lake Erie basin. This hypothesis is supported by modern erosion rates, which indicate appreciably higher erosion rates of glaciolacustrine clay than of till (Carter, 1976). Coarse lag deposits overlying till, particularly in the Fairport Harbor area, and beach deposits on the moraine off Erie, Pennsylvania (Williams and Meisburger, 1982), appear to be good evidence for wave erosion during times of lower lake levels. Lewis (1966) found coarse deposits overlying a smooth till and glaciolacustrine clay surface along the north shore of Lake Erie; he interpreted the surface as a wave-cut terrace. This surface may be correlative with the broad till surface between Fairport Harbor and Cleveland.

#### 4. Postglacial Sediment.

Holocene sedimentation has contributed to a general filling in and flattening of the lake bottom. The sand deposits at Fairport Harbor, Lorain-Vermilion, and Cedar Point (Williams, et al., 1980) are likely the product of different depositional environments and different ages ranging from the early Holocene, when lake levels were lower than at present, to the late Holocene. Two radiocarbon ages were obtained from wood fragments in core 62 at Fairport Harbor (T.L. Lewis, Cleveland State University, personal communication, 1979). At a depth of 414 centimeters below the lake floor the radiocarbon age is  $8250 \pm 145$  years B.P.; between 210 and 228 centimeters the radiocarbon age is  $4020 \pm 190$  years B.P. These ages indicate that the deposit was built up during a rising lake level, possibly the result of a combination of fluvial, deltaic, and beach-nearshore environments. Aside from the sand deposits, the finer grained sediments appear, for the most part, to reflect present-day wave and current conditions in the lake, perhaps largely related to fetch and prevailing winds as hypothesized by Thomas, et al. (1976).

#### V. SUMMARY

The southern Ohio waters of Lake Erie (commonly from 1 to 7 kilometers offshore) between Conneaut and Marblehead were surveyed in August of 1977 and 1978. Primary survey data consist of 576 kilometers of seismic reflection trackline

profiles, taken in 1977, and 58 vibracores ranging from 0.7 to 6.1 meters long, taken in 1978. About 23 percent of Ohio's part of Lake Erie was covered by the survey.

Shale underlies most of the survey area. The shale is overlain by glacial tills and by postglacial deposits. The surfaces of all the units slope lake-ward. In general, the shale is exposed nearest the shore and succeeded offshore by till and postglacial deposits. The shale surface is irregular in comparison with the till and postglacial deposit surfaces and its slopes range from 5 to 20 meters per kilometer. Basal till and flow till were identified in many of the cores. An olive-gray basal till was found over much of the area and a yellowish-gray basal till was found in the Lorain-Vermilion area. Some of the tills contain interlaminated silts and clays (varves?), and three cores contain both basal till and flow till. The tills are made up largely of silt- and clay-size particles composed of quartz and illite. The till surface is much flatter and more uniform than the underlying shale surface and its slopes range from 1 to 4 meters per kilometer. Overall, the till thickens lakeward at about 5 meters per kilometer.

On the basis of cores and echo character on the seismic records, four principal postglacial deposits were defined: sand, muddy sand, sandy mud, and mud. At about 9 kilometers offshore, the stretch from Conneaut to Fairport Harbor is characterized by postglacial sediment thicknesses ranging from 10 to 16 meters; the stretch from Fairport Harbor to Cleveland is characterized by a lack of postglacial sediment. At about 5 kilometers offshore, the area from Cleveland to Lorain is characterized by postglacial sediment thicknesses ranging from 0 to 2 meters; from Lorain to Vermilion the thicknesses range from 4 to 5 meters. In general, the finest sediment is found closer to shore and in shallower water west of Cleveland.

The irregular shale surface in concert with the characteristics of the buried river valleys implies an irregular surface before Pleistocene Glaciation. The relatively smooth till surface is likely the product of several Wisconsinan glacial advances and retreats. The physical variations in the till in the cores, as well as the internal seismic reflectors in the till, indicate that multiple tills were emplaced. The topographic lows on the till surface off Fairport Harbor and Lorain-Vermilion imply stream erosion, and the scarcity of glacio-lacustrine clay implies stream and wave erosion following retreat of the last Wisconsinan glacier. The postglacial deposits accumulated during a rising lake level from fluvial, deltaic, and lacustrine processes. The sedimentary deposits on the lake floor reflect Pleistocene and Holocene processes as well as the configuration and nature of the underlying rock and till. Present-day waves and currents tend to erode and rework the shale, tills, and postglacial deposits in high-energy environments. Subsequent deposition of these sediments in low energy environments is obscuring evidence of previous low water stages.

## APPENDIX A

### CORE SEDIMENT DESCRIPTIONS

This appendix contains core sediment descriptions, based on both megascopic and microscopic examinations. Color is based on damp samples as referred to the Munsell color system (Munsell Soil Color Charts, 1954 ed., Munsell Color Co., Inc., Baltimore, Md.); grain size is based on the Wentworth size scale.

The marks on the left side of the stratigraphic log are placed at the mid-points of sampled intervals used for size analysis. The type of analysis is designated by the following codes (size data are tabulated in App. B):

R - Rapid Sand Analyzer (RSA)

S - Sieve analysis

V - Visual Accumulation Tube (VAT)

P - Pipet analysis

The letter B indicates the bottom of the core.

Sediments are grouped into the following six basic categories for logging (minimum unit thickness shown is 20 centimeters):

	Mud		Silt
	Sand		Clay
	Muddy Sand		Gravelly Clay

Column descriptions for core sediments are:

NW = midpoint of sampled sediment used for natural water determinations (interval usually 10 centimeters long); number is: weight of wet sediment minus weight of dry sediment divided by weight of wet sediment times 100.

P = penetrometer measurement (in tons per square inch or kilograms per square centimeter).

SV = shear vane measurement (in tons per square inch or kilograms per square centimeter); PF = plastic flow.

Water depths are the surveyed water depths; these depths were about 1 meter above low water datum (LWD) for Lake Erie.

Mud (5GY 4/1, dark greenish gray)  
 Muddy, very fine sand (5GY 3/1, dusky greenish gray)  
 Sandy silt (5Y 3/1, dusky olive gray)

CORE NO. 53-538  
 WATER  
 DEPTH: 13.4 m (44.0 ft)  
 RECOVERY: 115 cm

Mud (5GY 3/1, dusky greenish gray)  
 Silt (5Y 4/1, olive gray) with minor sand laminations  
 Well-sorted fine sand (5Y 3/1, dusky olive gray)  
 Muddy, fine to medium sand (5Y 3/1, dusky olive gray)

CORE NO. 52-438  
 WATER  
 DEPTH: 16.0 m (52.5 ft)  
 RECOVERY: 256 cm

## APPENDIX B

### GRANULOMETRIC DATA AND CUMULATIVE CURVE PLOTS

The samples in this appendix are identified by core number and sample interval below the top of the core. Locations of the samples in each core are shown in Appendix A.

#### 1. Rapid Sand Analyzer (RSA).

Data include the frequency and cumulative percent at 0.5-phi intervals. Also included are median, mean, standard deviation, skewness, and kurtosis for each sample. Experience has shown that grain-size values from RSA analyses are consistent and slightly coarser than results of sieve analyses of identical samples; therefore, empirical relations for converting RSA means and standard deviation to sieve analyses equivalents have been determined. The relationships, developed from RSA and sieve analyses at a 0.25-phi interval are (Williams, Prins, and Meisburger, 1979):

$$\text{Mean:} \quad \bar{X}_{\phi}^{\text{sieve}} = 1.0735 \bar{X}_{\phi}^{\text{RSA}} + 0.1876$$

$$\text{Standard deviation:} \quad \sigma_{\phi}^{\text{sieve}} = 1.4535 \sigma_{\phi}^{\text{RSA}} - 0.146$$

#### 2. Sieve Data.

Data include frequency and cumulative percent at 0.5-phi intervals from samples estimated to have gravel percentages over 10 percent.

#### 3. Cumulative Curves.

Sieve data plotted at 0.5-phi intervals.

#### 4. Pipet Analysis.

Percentages of sand, silt, and clay are included for each sample.

#### 5. Visual Accumulation Tube (VAT) (Guy, 1969).

Percentages of sand and silt-clay as well as mean grain size are included for each sample.

DISTRIBUTION OF SIZE CLASSES BY FREQUENCY PERCENTAGES (RSA)

<sup>1</sup>Abundance: + is abundant; 0 is common; - is rare.

## APPENDIX F

### SEDIMENT THICKNESS DATA FROM SEISMIC RECORDS

#### Seismic velocities:

water	$\bar{v} = 1.54$ meters per millisecond
postglacial sediments	$\bar{v} = 1.3$ meters per millisecond
till	$\bar{v} = 1.8$ meters per millisecond

Water depth is survey water depth (about 174.3 meters), which is 1 meter above low water datum (IGLD, 1955).

- a. Postglacial sediment and till thicknesses were measured at two confidence levels. Those followed by an "a" (the first confidence level) are those in which the reflector was well defined on the seismic record; unmarked thicknesses are those in which the reflector was not well defined on the seismic record yet whose position could be reasonably well inferred from the overall geologic setting and character of the reflector.
- b. The letter "b" indicates thickness data not available because (1) both postglacial sediment and till thicknesses could not be measured because of difficulty in interpreting the seismic records (in this case water depth was not measured), or (2) the seismic reflection record for the fix is missing.

#### All thicknesses in meters

T = trace of material, <0.5 meter, but enough to change surface echo character.

x = thickness not measurable because of lack of lower reflector.

Fix No.	Water depth	Postglacial sediment thickness	Till thickness	Fix No.	Water depth	Postglacial sediment thickness	Till thickness

## APPENDIX H

## CALCULATIONS OF SEISMIC VELOCITY IN POSTGLACIAL SEDIMENTS

Core No.	Postglacial sediment thickness (m)	Time to Pleistocene reflector (ms)	Seismic speed  (m/ms)
54	1.41	3.00	0.94
55	3.90	5.50	1.42
60	5.57	6.24	1.78
61	3.05	6.00	1.02
77	1.54	2.50	1.23
78	1.25	2.00	1.25
79	0.80	1.50	1.07
84	2.98	4.00	1.49
85	3.90	5.00	1.56
97	1.02	1.50	1.60
98	3.03	2.00	1.21
99	2.18	3.50	1.25

## APPENDIX I

COMPARISON OF POSTGLACIAL SEDIMENT THICKNESSES  
AS MEASURED FROM THE CORES AND CALCULATED FROM THE SEISMIC RECORDS

Core No.	Thickness		
	Seismic (m)	Measured (m)	Difference (m)
51	2.5	3.7	1.2
54	2.0	1.4	-0.6
55	3.5	3.9	0.4
60	4.0	5.6	1.6
61	4.0	3.0	-1.0
73	0	0.3	0.3
75	0	0.2	0.2
76	1.0	0.6	-0.4
77	1.5	1.5	0.0
78	1.5	1.3	-0.2
79	1.0	0.8	-0.2
81	3.5	3.0	-0.5
84	2.5	3.0	0.5
85	3.5	3.8	0.3
86	2.0	2.1	0.1
92	1.0	1.1	0.1
95	4.0	4.0	0.0
96	3.0	2.5	-0.5
97	1.0	1.0	0.0
99	2.5	2.2	-0.3

<p>Carter, Charles H. Regional geology of the southern Lake Erie (Ohio) bottom: A seismic reflection and vibracore study / by Charles H. Carter, S. Jeffress Williams...[et al.].--Fort Belvoir, Va. : U.S. Army, Corps of Engineers, Coastal Engineering Research Center, Springfield, Va. : available from NTIS, 1982. [109] p. : ill. ; 28 cm.--(Miscellaneous report / Coastal Engineering Research Center ; no. 82-15). Cover title. "December 1982." Report is one of three reports which describe results of the Inner Continental Shelf Sediment and Structure (ICONS) study of southern Lake Erie. The primary objective is to locate and delineate sand and gravel deposits suitable for beach nourishment and restoration. 1. Geomorphology. 2. Lake Erie. 3. Sand resources. 4. Sediments. 5. Seismic reflection. I. Title. II. Williams, S. Jeffress. III. Coastal Engineering Research Center (U.S.). IV. Series: Miscellaneous report (Coastal Engineering Research Center (U.S.)); no. 82-15.
